Introduction: T-peak-to-T-end interval (T_{pe}) based indices have shown value in quantifying the increase in ventricular repolarization dispersion (VRD) that has been associated with ventricular arrhythmias (VA). A time-warping-based index, d_{w,T_{pe}}, quantifying morphology changes within the T-peak-to-end interval, has previously demonstrated utility in predicting VA in a 40-min porcine infarction model. This work assesses the contribution of d_{w,T_{pe}} as predictor of ventricular fibrillation (VF) episodes in a long-time open-chest porcine infarction model.

Methods: Oclusion and pre-occlusion (control stage) body surface ECG recordings from 20 pigs undergoing a 40-minute open-chest coronary occlusion were analyzed. The d_{w,T_{pe}} index quantifies the morphological differences between the T_{pe} morphology at different stages of the occlusion and at the control preoclussion recording. Results were compared with the classical T_{pe} index.

Results: From 20 pigs, 8 suffered a delayed (later than 7 min from occlusion) VF episode (VF-group). d_{w,T_{pe}} remained stationary at control recordings, with a median [IQR] values of 0 [1.87] ms. During occlusion, the absolute value of d_{w,T_{pe}} followed a gradual increasing trend as ischemia progressed. At 0-5, 5-10, 10-15 and 15-20 minutes after the occlusion onset, d_{w,T_{pe}} absolute median values were significantly higher in the VF group than in the non-VF group (Kruskal-Wallis test), with values of 10.2, 11.7, 18.2 and 19.0 vs 1.8, 2.4, 3.2 and 2.4 ms, and p-values of 0.017, 0.041, 0.045 and 0.013, respectively (see Figure). The T_{pe} index did not present significant differences in any of the intervals between VF and non-VF groups.

Conclusion: The time-warping-based morphology index, d_{w,T_{pe}}, can monitor ischemia-induced changes. Larger dynamic increase of the d_{w,T_{pe}} index during ischemia progression is associated with VF episodes and suggest the need further clinical studies in humans.
